## ABSTRACT

Eastern hemlock, *Tsuga canadensis*, is currently experiencing widespread mortality due to the invasive hemlock woolly adelgid (HWA; *Adelges tsugae*). Eastern hemlock looper (*Lambdina fiscellaria*), another hemlock pest, is a native lepidopteran that has reached outbreak levels in the past. While these insects share a host and overlap in range, little is known about their interactions. Research has shown that HWA infestation increases methyl salicylate concentrations (an indicator of the induction of the salicylic acid pathway) in hemlock tissue while hemlock looper, a chewing insect, likely elicits the jasmonic acid pathway. While plants are capable of inducing both of these defensive pathways, they have been found to be mutually antagonistic. We tested the hypothesis that looper performance is affected by prior HWA infestation and plant defense. Specifically, we hypothesized that looper larvae would perform better on HWA infested hemlock foliage. Looper were reared to pupation on hemlock foliage that was either infested or uninfested with HWA. Within those treatments, groups of foliage were sprayed with defensive elicitors to induce either the jasmonic- or salicylic-acid pathway. We also analyzed total phenolic content and terpenoid levels in host needle tissue in all treatments. Application of the chemical elicitors negatively affected looper survival, and their impact was altered by HWA presence. Larval survival was significantly lower in treatments where both HWA and elicitor were present. In contrast, larval survival was higher in the HWA-infested control treatment in comparison to the uninfested treatment. This demonstrates a strong interactive effect between HWA and elicitor. The combined effect of elicitor and HWA infestation led to increases in both phenolics and terpenoids, suggesting a major role for these compounds in plant defense. This study demonstrates

the complex host-mediated interactions occurring between a native and an invasive insect which may aid in the further study of insect interactions.

## **ACKNOWLEDGEMENTS**

First and foremost, I would like to thank Dr. Evan Preisser, my major professor, for his continuous support and guidance throughout my time at the University of Rhode Island. I would also like to thank my committee members, Dr. Carol Thornber, Dr. Richard Casagrande, and Dr. Colin Orians, for contributing so much to the design and analysis of this project. Thanks to Dr. Larry Englander for chairing the committee and always expressing genuine interest. I am grateful to Drs. Chad Rigsby and Robert Schaeffer for putting in countless hours in the laboratory and answering my many questions regarding plant chemistry. Emma Shoemaker and Alex Baranowski, thank you both for being so actively involved throughout the project. Lisa Tewksbury, your assistance in the Biological Control Lab was truly invaluable. And a huge thanks to Claire Wilson, Elizabeth Whitney, and Katharine Harrison for not only supporting me intellectually, but for constantly brightening the office as well as my mood. A special thanks to my husband Paul McDivitt for sitting through many practice talks and actively delving into the world of the hemlock woolly adelgid with me. This project would not have been possible without funding from the National Science Foundation, as well as support from the University of Rhode Island through graduate teaching assistantships.

## **PREFACE**

The following thesis has been submitted in manuscript format following the formatting guidelines of the journal *Ecology*.

## ABSTRACT

Eastern hemlock, *Tsuga canadensis*, is currently experiencing widespread mortality due to the invasive hemlock woolly adelgid (HWA; *Adelges tsugae*). Eastern hemlock looper (*Lambdina fiscellaria*), another hemlock pest, is a native lepidopteran that has reached outbreak levels in the past. While these insects share a host and overlap in range, little is known about their interactions. Research has shown that HWA infestation increases methyl salicylate concentrations (an indicator of the induction of the salicylic acid pathway) in hemlock tissue while hemlock looper, a chewing insect, likely elicits the jasmonic acid pathway. While plants are capable of inducing both of these defensive pathways, they have been found to be mutually antagonistic. We tested the hypothesis that looper performance is affected by prior HWA infestation and plant defense.

Specifically, we hypothesized that looper larvae would perform better on HWA infested hemlock foliage. Looper were reared to pupation on hemlock foliage that was either infested or uninfested with HWA. Within those treatments, groups of foliage were sprayed with defensive elicitors to induce either the jasmonic- or salicylic-acid pathway. We also analyzed total phenolic content and terpenoid levels in host needle tissue in all treatments. Application of the chemical elicitors negatively affected looper survival, and their impact was altered by HWA presence. Larval survival was significantly lower in treatments where both HWA and elicitor were present. In contrast, larval survival was higher in the HWA-infested control treatment in comparison to the uninfested treatment. This demonstrates a strong interactive effect between HWA and elicitor. The combined effect of elicitor and HWA infestation led to increases in both phenolics and terpenoids, suggesting a major role for these compounds in plant defense. This study demonstrates

the complex host-mediated interactions occurring between a native and an invasive insect which may aid in the further study of insect interactions.

*Keywords:* hemlock woolly adelgid, hemlock looper, phenolics, terpenoids, *Tsuga canadensis*, plant defense, salicylic acid, jasmonic acid.

## INTRODUCTION

Most long-lived plant species must withstand both simultaneous and sequential attacks from multiple herbivores. Interactions between herbivores that share a host can take several forms. Insects that feed at the same time can interact either directly (e.g., interference competition) or via their impact on the shared resource (e.g., exploitative competition) (Park 1948, Mattson 1986, Denno et al. 1995). For herbivores that differ in their phenology, these effects are necessarily asymmetric - feeding by an earlier-arriving insect species, for instance, may affect a later-arriving herbivore via changes in the host plant. Such herbivore-induced changes may negatively impact the later-arriving species by increasing plant defense or decreasing host quality (Faeth 1986, Harrison and Karban 1986); it is also possible, however, for the early-arriving species to benefit the later-arriving one via decreases in plant defense (Rodriguez-Saona et al. 2010, Soler et al. 2012).

The induced production of chemical compounds is a commonly-used defense against herbivory (Karban and Baldwin 1997). Two of the most well-studied plant defense pathways are the salicylic acid (SA) and jasmonic acid (JA) pathways. While the SA pathway is often induced by pathogen infection and piercing-sucking insects (Malamy et al. 1990, Kaloshian and Walling 2005), the JA pathway is more closely

associated with defense against chewing herbivores (McCloud and Baldwin 1997, Walling 2000). While plants can induce both the SA and JA pathways, the two pathways are often antagonistic; the induction of one precludes expression of the other (Kunkel and Brooks 2002). This creates the possibility for defense-signaling crosstalk within plants attacked by multiple herbivores. SA pathway expression in pathogen-attacked plants, for instance, may suppress the JA pathway and increase susceptibility to subsequent herbivory. Cases where JA-SA signaling crosstalk has impacted insect performance have been documented in many plant species (Cipollini et al. 2004, Zhang et al. 2013, Schweiger et al. 2014).

The hemlock woolly adelgid (*Adelges tsugae* Annand; 'HWA') is a sessile herbivore native to Japan that was first recorded in the eastern United States in the 1950s (Havill et al. 2006). In the northern portion of its invaded range, this aphid-like insect feeds solely on eastern hemlock (*Tsuga canadensis* [L.] Carriere) by inserting its stylet into the base of a needle and feeding on xylem ray parenchyma cells (Young et al. 1995). Eastern hemlocks are highly susceptible to HWA (Montgomery et al. 2009) and trees quickly decline in health. HWA can kill even mature trees in as little as four years (McClure 1991), with some HWA-infested stands experiencing over 95% hemlock mortality (Orwig and Foster 1998).

Although HWA poses a major threat, it is not the only insect capable of causing substantial hemlock mortality. The eastern hemlock looper (*Lambdina fiscellaria* Guenée; 'looper') is a native lepidopteran whose larvae defoliate hemlocks and can cause tree mortality after just four years of severe defoliation (Hudak et al. 1978). Although the looper and HWA share a host and co-occur in southern New England, very little is known

about their interplay (Wilson et al. 2015). The potentially dramatic impacts of both herbivores on eastern hemlock forests suggests, however, that their interactions may be extremely important.

The hemlock woolly adelgid and looper differ in a number of respects. While both insects begin feeding in spring, HWA typically settle on foliage several weeks before looper larvae emerge. In addition, HWA are sessile xylem feeders while looper larvae are mobile folivores. These differences create the potential for plant-mediated interactions between HWA and the looper: previous research indicates that looper larvae may perform better on HWA-infested foliage (Wilson et al. 2015). While the mechanistic basis for these results is unknown, it may reflect herbivore-induced changes in plant defense.

Previous research has shown that HWA feeding increases the production of methyl salicylate, an ester of SA, in hemlock (Pezet and Elkinton 2014). By contrast, foliar-feeding looper larvae might be expected to increase expression of the JA pathway (Karban and Baldwin 1997, Kessler and Baldwin 2002, Van Wees et al. 2013). The co-occurrence of herbivores with different feeding modes on the same host suggests the potential for crosstalk between the SA and JA pathways. We hypothesized that looper larvae would have higher survival and perform better on foliage that had been previously infested with HWA. We also assessed whether spraying trees with chemicals designed to elicit either the JA or SA pathway would affect looper performance. We present research addressing the effects of HWA infestation on looper larval performance in the presence and absence of JA and SA pathway elicitors. In addition, an analysis of the phenolic and terpenoid content of needle tissue was performed in order to assess potential mechanisms for treatment differences in larval survival.

## METHODS

### *Larval Survival*

In spring 2015, we purchased 300 *T. canadensis* saplings (0.5-0.7 m height; 'hemlocks') from Vans Pines Nursery (West Olive, MI; derived from seed collected in PA). All hemlocks were herbivore-free and had not been treated with insecticides. After potting the hemlocks, we randomly selected half of them for HWA inoculation. Trees in the HWA treatment were inoculated in June 2015 by loosely tying two HWA-infested branches to each sapling, a standard protocol (Butin et al. 2007). We collected the HWA-infested branches from trees in the Middlesex Fells Reservation (Winchester, MA), the nearest site where we could find foliage infested with only HWA. The June 2015 inoculation occurred prior to hemlock woolly adelgid emergence, allowing sistens-generation crawlers to settle on the saplings. We held the 150 infested and 150 herbivore-free ('control') hemlocks outside the University of Rhode Island greenhouse complex (Kingston, RI), where they were watered as needed throughout summer and fall. We overwintered the trees outside, but covered them with winter protection fabric (170 grams per square yard; Griffin Greenhouse Supplies) for defense against extreme cold. We removed the winter blanket in early March 2016 and covered all of the hemlocks in insect-proof mesh (AG-15 Insect Barrier; Agribon) to prevent any early-emerging HWA crawlers from colonizing control trees.

In late March 2016, we chose thirty trees that had uniformly high HWA densities and then chose thirty uninfested trees that were similar in size to each other and to HWA-infested trees for the experiment. Ten randomly-chosen trees within each 30-tree group were assigned to one of three elicitor treatments (ethanol, salicylic acid, or jasmonic

acid), for a total of six 10-tree treatments. We determined appropriate elicitor concentrations on the basis of published literature (Moreira et al. 2009, Sampedro et al. 2011, Moreira et al. 2012) and a series of pilot experiments. Each tree was hand-sprayed until runoff with either 40 mM MeJA (methyl jasmonate), 20  $\mu$ M ASM (acibenzolar-S-methyl) (both with 2.5% ethanol as the carrier solution), or 2.5% ethanol, which served as the no-elicitor treatment. The spraying began in mid-May and continued weekly for four weeks. Although we had planned to apply the elicitor treatments throughout the experiment, we were forced to stop when hemlocks in the HWA + JA treatment turned brown and lost a large fraction of their needles (see Supporting Information, Fig. S1).

In early May, we obtained *L. fiscellaria* ('looper') eggs from the Laurentian Forestry Centre of the Canadian Forest Service (Québec City, QC, Canada). Movement of the eggs from Canada to the United States, and our subsequent work with them, was covered under APHIS permit P526P-14-01875. Upon arrival at URI, all eggs were placed in a growth chamber (15°C, 75% RH, 16L/8D cycle) and monitored daily.

The experiment began in late May when the looper eggs began hatching. After putting a small piece of floral foam in each of 60 liter-size Ball Mason jars, we clipped a 15-cm piece of foliage from each tree and placed it in a water-filled floral tube (7.6 cm standard; Royal Imports) that we stuck into the foam. Hatchling larvae were randomly assigned to one of the 60 foliage-filled jars until each jar contained five larvae (300 total larvae). Each jar was covered with a fine white mesh (~0.5 mm; nylon) to allow ventilation but prevent escape. All 60 jars were kept in the growth chamber under the conditions described above. All jars were rotated weekly to control for potential microclimatic differences. Each jar was considered a replicate (60 total).

We assessed looper performance by measuring larval survival, mass, and days to pupation. Eight days after the experiment began, we counted the surviving larvae in each jar and weighed them together using a Mettler Toledo scale ( $\pm 0.001$  mg) in order to determine average live larval mass per jar. The larvae were then returned to their respective jar in the growth chamber. We recorded survival 13 times (~weekly) throughout the experiment; larval mass was recorded on days 15, 28, 39, 49, and 62. All larvae were given fresh foliage seven days after the start of the experiment, then as often as necessary throughout the experiment. The experiment ended in late July, when the nine surviving larvae that had failed to pupate were weighed and frozen at  $-20^{\circ}\text{C}$  until autoclaving as per our APHIS permit.

### ***Chemical Defenses of Needle Tissue***

On June 6, 2016, three randomly-selected ~10 cm twigs were clipped from each tree, stored in aluminum foil packets, and immediately placed in liquid nitrogen. Packets were subsequently stored at  $-80^{\circ}\text{C}$  until extractions were performed. For extractions, needles and twigs were separated and the two tissue types ground to powder in liquid nitrogen. Approximately 100 mg of powdered needle tissue was placed in 1.5 mL microtubes, followed by the addition of 0.5 mL of 100% methanol. Tubes were incubated for 24 hours with occasional vortexing, after which the  $9,000 \times g$  supernatant was removed and placed into new 1.5 mL tubes. The process was repeated and supernatants were eventually combined.

Total soluble phenolics were quantified according to Cipollini et al. (2011). Briefly, 20  $\mu\text{L}$  methanol extract was diluted with 75  $\mu\text{L}$  DI  $\text{H}_2\text{O}$ , followed by an additional 500  $\mu\text{L}$  DI  $\text{H}_2\text{O}$ . After adding 37.5  $\mu\text{L}$  of Folin's Phenol Reagent (Sigma), the

tube was allowed to incubate at room temperature for 5 minutes. Afterwards, 37.5  $\mu\text{L}$  1 M  $\text{NaCO}_3$  was added and the tube incubated at room temperature for one hour. The absorbance of 200  $\mu\text{L}$  aliquots in duplicate wells of Greiner UV-Star<sup>®</sup> flat-bottomed 96-well microplates (Monroe, North Carolina) of the reaction solutions were quantified at 725 nm using a SpectraMAX 190 microplate reader (Molecular Devices, Sunnyvale, CA) against a standard curve of gallic acid. Soluble phenolics were expressed as mg/g fresh weight (FW).

For terpenoids, the spectrophotometric procedure described by Ghorai et al. (2012) was used. A 200  $\mu\text{L}$  aliquot of methanol extract was added to a 2 mL microtube containing 1.5 mL chloroform, followed by the addition of 100  $\mu\text{L}$   $\text{H}_2\text{SO}_4$ . After the samples were incubated for two hours in the dark, 1 mL of the top layer was removed, replaced with 1 mL 100% methanol, and the tubes were vortexed to solubilize the red precipitate. The absorbance of the solution was quantified at 538 nm against a standard curve of linalool, and terpenoids were expressed as mg/g FW.

### ***Statistical Methods for Analysis of Larval Survival***

All statistical analyses were performed using R Statistical Software (R Core Team 2016). Due to the unexpected decline of the HWA-infested trees sprayed with the JA-elicitor, we ceased applying elicitors after four weeks, as described previously. Thus, in assessing the effects of the elicitor treatments on larval survival, we analyzed the first six data points (through Julian day 173), which coincides with the last application of the SA- and JA-elicitors; larval survival after this point would not have likely been impacted by these applications. To assess the impacts of HWA infestation of host material and elicitor applications, a repeated measures analysis of variance (rm-ANOVA) was employed.

Survival data were arcsine-square root transformed (Lindroth et al. 1990). Percent larval survival in a given jar was the response variable and HWA infestation, elicitor application, and the interaction between the two were the predictor variables. To estimate treatment differences, individual treatment combinations were used as the predictor variable and percent survival as the response variable in a linear mixed-effect model with sampling date as the random effect. A post-hoc separation of means was then performed on this model via a Tukey test using the simultaneous tests for general linear hypotheses ('glht') function, part of the 'multcomp' package (Hothorn et al. 2008) in R.

### ***Statistical Methods for Defense Chemistry and Nutritional Attributes***

All statistics were performed using R Statistical Software (R Core Team 2016). The Shapiro-Wilk normality test was used to confirm data normality and the Dixon test was used to identify and remove outliers using the 'Outliers' package in R (Komsta 2011). An analysis of variance (ANOVA) was used to determine the significance of HWA infestation, hormone application, and the interaction between the two, with these factors as predictor variables and soluble phenolics or terpenoids as response variables. If either the interaction or hormone application predictor variables were significant, post-hoc Tukey's HSD was used to determine which treatments differed from each other.

## **RESULTS**

### ***Larval survival***

HWA infestation tended to increase larval survival over time ( $F_{1,324}=5.32$ ,  $P=0.069$ ) according to the results of the repeated measures ANOVA (Table 1) (Figure 1). There was a significant negative effect of both the chemical elicitor treatment ( $F_{2,324}=10.30$ ,  $P=0.004$ ) and the interaction between HWA infestation and elicitor ( $F_{2,324}=7.90$ ,

P=0.009) on survival. The post-hoc analysis revealed that the JA treatment significantly lowered larval survival (P=0.007) in comparison to both the ethanol and SA treatments. The post-hoc analysis of the interactive effects revealed that the HWA-infested + JA (P = 0.017) and the HWA-infested + SA (P = 0.016) treatments had significantly lower survival than the HWA-infested + ethanol treatment. No other treatment had a statistically significant effect on survival relative to other treatment combinations. There was also no significant effect of any treatment on larval mass (Table 1).

### ***Defense Chemistry and Nutritional Attributes***

HWA had a marginally significant effect on soluble phenolics ( $F_{1,54} = 3.27$ ,  $P = 0.076$ ) and terpenoids ( $F_{1,54} = 3.07$ ,  $P = 0.086$ ), while elicitor application had a significant positive effect on both phenolics ( $F_{2,54} = 71.62$ ,  $P < 0.001$ ) and terpenoids ( $F_{2,54} = 4.02$ ,  $P = 0.024$ ) with a nearly significant interaction effect on terpenoids ( $F = 3.05$ ,  $P = 0.056$ ) (Table 1). For soluble phenolics, JA application significantly increased levels, regardless of HWA infestation; in contrast, SA application significantly increased levels only in the presence of HWA (Figure 2A). SA application significantly increased total terpenoids when combined with HWA infestation (Figure 2B).

## **DISCUSSION**

Looper larvae fed HWA-infested foliage tended to have higher survival than those reared on uninfested foliage. The presence of elicitors also affected survival, and their impact was altered by HWA presence (Table 1). Looper larvae fed HWA-infested foliage treated with either the JA or SA elicitor had significantly lower survival rates than all other treatment combinations (Figure 1). We also analyzed phenolic and terpenoid content in needle tissue, both of which have been shown to negatively affect herbivorous

insects (Feeny 1968, Bezemer et al. 2003, War et al. 2012) and play a major role in conifer resistance. The fact that both phenolic content and terpenoid levels increased with MeJA and SA application is consistent with our general understanding of the role that both metabolites play in herbivore-induced defense in hemlock.

The application of SA on uninfested foliage did not significantly increase levels of phenolics or terpenoids, and neither did HWA infestation alone. However, the combined presence of SA and HWA increased levels of both metabolites while decreasing larval survival, suggesting a causative connection between these two variables. This result may be due to defensive priming, a plant's increased readiness to induce defenses (Conrath 2009). This is often mediated by herbivore-inducible plant volatiles (HIPVs) which are frequently produced in direct response to herbivory (Kim and Felton 2012, War et al. 2012). The production of HIPVs in the attacked part of the plant can function as a signaling cue and prime defensive responses in the rest of the plant (Heil and Silva Bueno 2007, Rodriguez-Saona et al. 2009). Studies have shown plant priming can alter a variety of defensive responses, including the accumulation of secondary metabolites (Kessler et al. 2006, Hirao et al. 2012). If the initial HWA infestation defensively primed the hemlock trees, this would explain why the subsequent addition of elicitors induced greater defense, i.e., higher phenolic and terpenoid concentrations. While the potential for defensive priming is intriguing, further study is necessary to confirm that it is in fact occurring.

Our JA elicitor increased phenolic, but not terpenoid, concentrations. Applying MeJA to uninfested hemlocks increased foliar phenolics but did not alter larval survival. As a result, phenolic and terpenoid concentrations do not appear to explain low larval

survival in the JA + HWA treatment. It is possible that JA-driven decreases in larval survival are due to factor(s) we did not quantify, such as plant nutritional quality or another defensive compound. Future research might consider analyzing factors such as carbon, nitrogen, and water content, as well as starch and tannin levels, in order to provide additional insight into interplay between plant chemistry and larval survival.

We were surprised that HWA infestation alone did not significantly alter phenolic or terpenoid levels. We did, however, find that the impact of both elicitors was only apparent when applied to HWA-infested foliage. Adelgid infestation increased survival in the absence of elicitors but decreased it in their presence: both the HWA + JA and HWA + SA treatments had significantly lower survival than the HWA + ethanol treatment. While the strong HWA by elicitor interaction is intriguing, the broad-scale chemical analyses we conducted proved insufficient to provide a clear and convincing explanation. Further hemlock tissue analyses, such as those mentioned in the previous paragraph should be done in conjunction with measures of larval survival. Additional analyses of looper larval chemistry might also improve our understanding of their physiological responses to the different treatments.

The increasing number of invasive forest pests in North America (Aukema et al. 2011) has made research addressing their direct and indirect effects increasingly important. Invasive species are estimated to cost the United States over \$120 billion annually in damages (Pimental et al. 2005). There are also significant ecological impacts of the introduction of non-native species. Invasive species are widely recognized as one of the leading causes of global species decline (Wilcove et al. 1998, NRC 2002). Studying invasive insects, for example, and their impacts on host species in their invaded

range is certainly important, however, the resulting effects of invasion often extend beyond these immediate interactions (Kenis et al. 2009). It is increasingly important, therefore, to include potential secondary interactions and impacts when studying invasive species.

Eastern hemlock is an ecologically important forest tree and is considered a foundation species (Ellison et al. 2005). The presence and abundance of *T. canadensis* not only defines a hemlock forest, but greatly influences both terrestrial and aquatic habitats (Snyder et al. 2002, Tingley et al. 2002). It is currently experiencing widespread mortality due to the invasive hemlock woolly adelgid (Orwig and Foster 1998). The eastern hemlock looper, another hemlock pest, is a native lepidopteran that has reached outbreak levels in the past (Hudak et al. 1978). Little is known about the relationship between these insects, such as how feeding by both may affect the chemical profile of their host, and how this plant-mediated interaction affects each species. While HWA infestation poses a significant threat to North America's hemlock forests, it is not an isolated system: the overlap of hemlock looper and HWA presents an opportunity to study interactions between a native herbivore and an invasive pest. Our results provide insight into the interactions occurring between two ecologically-important insect herbivores and their shared host plant. Further study may reveal additional insights applicable to other systems where native and invasive insect species interact.

## Tables

**Table 1:** Statistical analysis of the impact of HWA, elicitors, and their interactions on measured response variables.

<b>Response</b>	<b>Factor</b>	<b>F-value</b>	<b>df</b>	<b>P-value</b>
Larval Survival	HWA	5.32	1,324	0.069
	Elicitor	10.30	2,324	0.004*
	HWA x Elicitor	7.90	2,324	0.009*
Larval Mass	HWA	2.13	1,77	0.148
	Elicitor	0.98	2,77	0.380
	HWA x Elicitor	0.63	2,77	0.534
Soluble Phenolics	HWA	3.27	1,54	0.076
	Elicitor	71.62	2,54	<0.001*
	HWA x Elicitor	27.42	2,54	<0.001*
Terpenoids	HWA	3.07	1,54	0.086
	Elicitor	4.02	2,54	0.024*
	HWA x Elicitor	3.05	2,54	0.056

\*statistical significance (P<0.05)

## Figure Legends

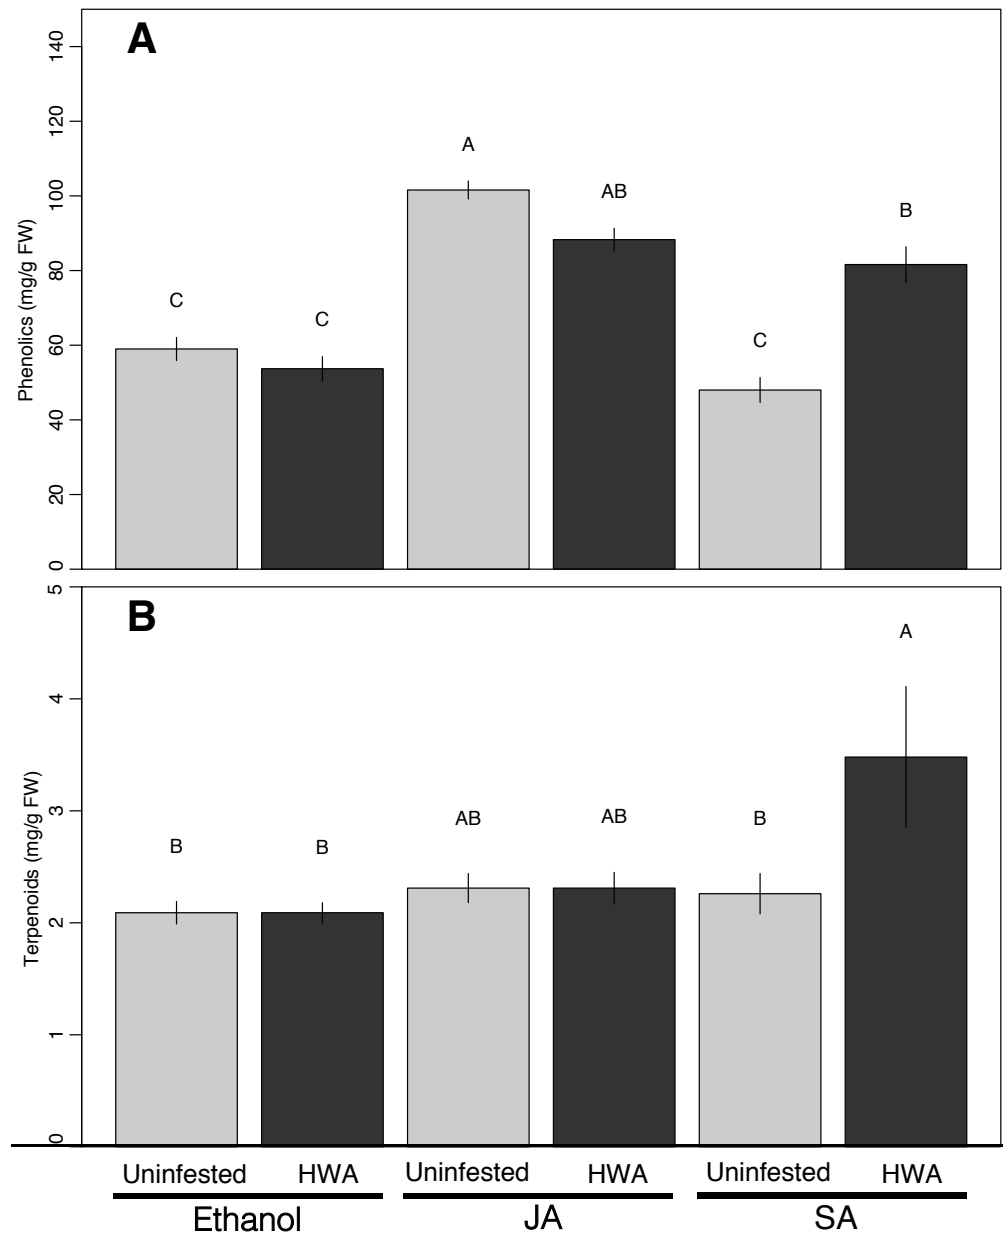

**Figure 1:** Percent looper larval survival over time. Dotted lines correspond to HWA-infested treatments; solid lines correspond to uninfested. Color denotes the chemical treatment (blue=ethanol, purple=JA, green=SA).

**Figure 2:** Defense chemistry of sampled needle tissue. Bars (mean  $\pm$  SEM) with same letter(s) are not significantly different by Tukey's test ( $P \leq 0.05$ ). **A:** Soluble phenolics (mg/g FW) of needle tissue sampled from each treatment. The application of JA significantly increased phenolics in both HWA-infested and uninfested treatments. The application of SA increased phenolics only in combination with HWA infestation. **B:** Terpenoids (mg/g FW) in needle tissue sampled from each treatment. The application of SA when combined with HWA infestation significantly increased total terpenoids.

Figure 1

**Figure 2**

## Supporting Information

**Figure S1:** Images of representative trees from each treatment group. Trees in the HWA+JA group (highlighted in yellow) suffered dramatic needle loss and were visibly more stressed than trees from all other treatment groups.
